ABSTRACT

In standard reinforcement learning, each new skill requires a manually-designed reward function, which takes considerable manual effort and engineering. Self-supervised goal setting has the potential to automate this process, enabling an agent to propose its own goals and acquire skills that achieve these goals. However, such methods typically rely on manually-designed goal distributions or heuristics to force the agent to explore a wide range of states. We propose a formal exploration objective for goal-reaching policies that maximizes state coverage. We show that this objective is equivalent to maximizing the entropy of the goal distribution together with goal reaching performance, where goals correspond to entire states. We present an algorithm called Skew-Fit for learning such a maximum-entropy goal distribution, and show that under certain regularity conditions, our method converges to a uniform distribution over the set of possible states, even when we do not know this set beforehand. Our experiments show that, when combined with existing goal-conditioned algorithms, Skew-Fit can learn a variety of manipulation tasks from images, including opening a door with a real robot, entirely from scratch and without any manually-designed reward function.

1 INTRODUCTION

How can we design an unsupervised reinforcement learning algorithm that automatically explores the environment and iteratively distills this experience into general-purpose policies that can accomplish new user-specified tasks at test time? For an agent to learn autonomously, it needs an exploration objective that visits as many states as possible. One way to formalize this notion in an objective is to quantify the entropy of the learned policy’s state distribution $H(S)$. However, a short-coming of this objective is that the resulting policy cannot be used to maximize user-defined rewards: such a policy only knows how to maximize state entropy. Thus, if we want to develop principled unsupervised reinforcement learning algorithms that result in useful policies, maximizing $H(S)$ is not enough. We need a mechanism that allows us to control the resulting policy to achieve new goals at test-time.

In this paper, we argue that this can be accomplished by performing goal-directed exploration. In addition to maximizing the state distribution entropy $H(S)$, we should be able to control where the policy goes by giving it a goal $G$ that corresponds to a desired state. Mathematically, this can be accomplished by stating that a goal-conditioned policy should also minimize the conditional entropy over the states given a goal, $H(S | G)$. This objective provides us with a principled way for training a policy to explore all states (“maximize $H(S)$”) such that the state that is reached can be controlled by commanding goals (“minimize $H(S | G)$”).

Directly using this objective is intractable, since it requires optimizing the marginal state distribution of the policy. However, we can avoid this difficult optimization by noting that our objective is the mutual information between the state and the goal, $I(S, G)$, which can be written as:

$$I(S, G) = H(S) - H(S | G) = H(G) - H(G | S).$$

1 Equal contribution.
2 Berkeley AI Research, University of California, Berkeley, Computer Science
Equation\(^1\) thus gives an equivalent objective for an unsupervised reinforcement learning algorithm: the agent should set diverse goals for itself (“maximize \(H(G)\)”) and learn how to reach these goals (“minimize \(H(G \mid S)\)”).

While the second objective—learning to reach goals—is the typical objective studied in goal-conditioned reinforcement learning [Kaelbling, 1993; Andrychowicz et al., 2017], most such methods omit the first term [Nair et al., 2018; Warde-Farley et al., 2018]. However, maximizing the diversity of goals is crucial for effectively learning to reach all possible states. In an unknown environment, acquiring such a maximum-entropy goal-sampling distribution is a challenging task: how can an agent set goal states when it does not even know which states are feasible? When the states are high-dimensional, as is the case for visual observations, sampling diverse goals from the unknown manifold of valid states presents a major challenge.

In this paper, we present Skew-Fit, a method for learning to model the uniform distribution over states, given only access to data collected by an autonomous goal-conditioned policy. Skew-Fit trains a generative model on previously visited states, skewing the training data so that rarely visited states are weighted more heavily, and using density estimates from the same generative model to measure the rarity of the states.

We empirically demonstrate that, when combined with existing methods for goal-conditioned RL, Skew-Fit allows us to autonomously train goal-conditioned policies that reach diverse states. We test this method on a variety of simulated vision-based robot tasks, as well as a real-world manipulation task that requires a robot to learn to open a door without any task-specific reward function. In these experiments, Skew-Fit reaches substantially better final performance than prior methods, and learns much more quickly. We demonstrate that our approach solves the real-world door opening task from scratch in about five hours, without any manually-designed reward function.

## Related Work

Prior work on training goal-conditioned policies assume that a goal distribution is available to sample from during exploration [Kaelbling, 1993; Schaul et al., 2015; Andrychowicz et al., 2017; Pong et al., 2018] or use a heuristics to sample goals [Colas et al., 2018b; Warde-Farley et al., 2018; Florensa et al., 2018a; Pére et al., 2018; Nair et al., 2018]. Our work is complementary to these methods: rather than focusing on training goal-reaching policies, we propose a principled method for maximizing the entropy of a goal sampling distribution, \(H(G)\).

Our method stands in contrast to exploration methods that give bonus rewards [Bellemare et al., 2016; Ostrovski et al., 2017; Tang et al., 2017; Savinov et al., 2018; Chentanez et al., 2005; Lopes et al., 2012; Stadie et al., 2016; Pathak et al., 2017; Burda et al., 2018b; Mohamed & Rezende, 2015; Chentanez et al., 2005]. These methods provide no mechanism for distilling the knowledge gained from visiting diverse states into flexible policies that can be applied to accomplish new goals at test-time: their policies visit novel states, and they quickly forget about novel states as others become more novel.
Other prior methods extract reusable skills in the form of latent-variable-conditioned policies \cite{Hausman2018, Gupta2018b, Eysenbach2019, Gupta2018a, Florensa2017, Gregor2016}. The resulting skills may be diverse, but they have no grounded interpretation, while our method can be used immediately after unsupervised training to reach diverse user-specified goals.

While some prior methods propose to choose goals based on heuristics \cite{Baranes2012, Veeriah2018, Colas2018a, Nachum2018, Florensa2018b}, our approach provides a principled framework for optimizing a concrete and well-motivated exploration objective, and can be shown to maximize this objective under regularity assumptions.

3 Problem Formulation

Standard RL considers a Markov decision process (MDP), which has a state space $S$, action space $A$, and unknown dynamics $p(s_{t+1} \mid s_t, a_t)$. Goal-conditioned RL also includes a goal space $G$, which we assume to be the same as the state space, $G = S$. A goal-conditioned policy $\pi(a \mid s, g)$ maps a state $s \in S$ and goal $g \in G$ to a distribution over actions $a \in A$, and its objective is to reach the goal, i.e. to make the current state equal to the goal.

While most goal-conditioned RL methods \cite{Kaelbling1993, Lillicrap2016, Schaul2015, Andrychowicz2017, Nair2018, Pong2018, Florensa2018a} focus on minimizing $H(G \mid S)$ by training an accurate goal-reaching policy, we focus on the problem of setting diverse goals or, mathematically, maximizing the entropy of the goal distribution $H(G)$. Let $U_S$ be the uniform distribution over $S$. Let $p_\phi$ be the goal distribution, i.e. $G \sim p_\phi$. Our goal is to maximize the entropy of $p_\phi$, which we write as $H(G)$. Maximizing $H(G)$ may seem as simple as choosing the uniform distribution to be our goal distribution: $p_\phi = U_S$. However, this requires knowing uniform distribution over valid states, which is not always trivial. In particular, we study the case where $S$ is a strict, unknown subset of $\mathbb{R}^n$, for some $n$. For example, if the states correspond to images viewed through a robot’s camera, $S$ corresponds to the (unknown) set of valid images of the robot’s environment, while $\mathbb{R}^n$ corresponds to all possible images, i.e. all arrays of a particular size. In such environments, sampling from the uniform distribution $\mathbb{R}^n$ is unlikely to correspond to a valid image of the real world.

We assume that we cannot sample arbitrary states from $S$, but that we can sample states by performing goal-directed exploration and observing new states. To be more concrete, we introduce a simple, abstract, and somewhat simplified model of this process. First, a goal $G \sim p_\phi$ is sampled from our goal distribution $p_\phi$. Then, the agent attempts to achieve this goal, which results in a distribution of states $S \in S$ seen along the trajectory. We abstract the entire MDP episode as some generative process and write the resulting marginal distribution over $S$ as $p(S \mid p_\phi)$.

For the derivation and analysis of our method, we assume we have access to an oracle goal reacher, meaning that $p(S \mid p_\phi) \approx p_{\text{emp}}(S)$. In practice, we of course use goal-conditioned RL rather than an oracle. In Section 4 we demonstrate that we can combine our method with an existing goal-conditioned RL algorithm to jointly learn a goal-reaching policy and a goal sampling mechanism.

4 Skew-Fit: Learning a Maximum Entropy Goal Distribution

To learn a maximum-entropy goal proposal distribution, we present a method called Skew-Fit that iteratively increases the entropy of a generative model $p_\phi$. Given a generative model $p_{\phi_0}$, at iteration $t$, we would like to train a new generative model $p_{\phi_{t+1}}$ such that $p_{\phi_{t+1}}$ has higher entropy over the set of valid states. While we do not know the set of valid states $S$, we can sample states from $p(S \mid p_{\phi_t})$, resulting in an empirical distribution $p_{\text{emp}}$ over the states.

1Goal-conditioned RL can always be formulated as a standard RL problem by appending the goal to the state.

2Some authors define the goal as a feature of the state. It is straightforward to apply the analysis and method presented in this paper to this setting.

3We assume $S$ has finite volume so that the uniform distribution is well-defined.
and use this empirical distribution to train the next generative model \( p_{\phi_{t+1}} \). However, if we simply train \( p_{\phi_{t+1}} \) to model this empirical distribution, it may not necessarily have higher entropy than \( p_{\phi_t} \).

The intuition behind our method is quite simple: rather than fitting a generative model to our empirical distribution, we skew the empirical distribution so that rarely visited states are given more weight. See Figure \[4\] for a visualization of this process.

How should we skew the empirical distribution if we want to maximize the entropy of \( p_{\phi_{t+1}} \)? If we had access to the density of each state, \( p_{\text{emp}}(s) \), we could simply weight each state by \( 1 / p_{\text{emp}}(s) \). We could then perform maximum likelihood estimation (MLE) for the uniform distribution by using the following loss to train \( \phi_{t+1} \):

\[
\mathcal{L}(\phi) = \mathbb{E}_{s \sim U_S} \left[ \log p_\phi(S) \right] = \mathbb{E}_{s \sim p_{\text{emp}}} \left[ \frac{U_S(S)}{p_{\text{emp}}(S)} \log p_\phi(S) \right] \propto \mathbb{E}_{s \sim p_{\text{emp}}} \left[ \frac{1}{p_{\text{emp}}(S)} \log p_\phi(S) \right]
\]

where we use the fact that the uniform distribution \( U_S(S) \) has constant density for all states in \( S \). We avoid needing to model the entire MDP process, which requires an accurate model of both the dynamics and the goal-conditioned policy, by approximating \( p_{\text{emp}}(s) \) with our previous learned generative model: \( p_{\text{emp}}(s) \approx p(s \mid \phi_0) \approx p(\phi_0) \).

This procedure relies on importance sampling (IS), which can have high variance, particularly if \( p_{\phi_0}(s) \approx 0 \). We reduce this variance by weighing each state by \( p(\phi_0)(s)^\alpha \), for \( \alpha \in [-1, 0) \) rather than \( p(\phi_0)(s)^{-1} \). By choosing intermediate values of \( \alpha \), we can trade off the variance introduced by small \( p(\phi_0)(s) \) with the speed of the entropy increase to the goal distribution. Next, rather than relying on IS, we explicitly define a skewed distribution using the IS weights:

\[
p_{\text{skewed}}(s) = \frac{1}{Z_\alpha} p_{\text{emp}}(s) p(\phi_0)(s)^\alpha, \quad \alpha \in [-1, 0), \quad s \in \{S_n\}_{n=1}^N
\]

where \( Z_\alpha \) is the normalizing coefficient and \( p_{\text{emp}} \) is given by Equation \[2\]. Lastly, we fit the generative model at the next iteration \( p_{\phi_{t+1}} \) to \( p_{\text{skewed}} \) using standard MLE. Shown in Section \[A\] in the Appendix is that, for a range of values of \( \alpha \in [-1, 0) \), this procedure will always increase the entropy of the resulting distribution and eventually converge to a uniform distribution over valid states.

We also note that because \( p_{\phi_{t+1}} \approx p_{\text{skewed}} \), at iteration \( t + 1 \), one can sample goals from either \( p_{\phi_{t+1}} \) or \( p_{\text{skewed}} \). The final Skew-Fit procedure is visualized in Figure \[4\] and summarized in Algorithm \[1\].

**Algorithm 1 Skew-Fit**

1: for Iteration \( t = 1, 2, \ldots \) do
2: \( \) Collect \( N \) states \( \{S_n\}_{n=1}^N \) by sampling \( G \) from \( p_{\phi_t} \) (or \( p_{\text{skewed}} \)) and rolling out policy.
3: \( \) Construct skewed distribution \( p_{\text{skewed}} \) (Equation \[3\]).
4: \( \) Fit \( p_{\phi_{t+1}} \) to skewed distribution \( p_{\text{skewed}} \) using MLE.
5: end for

\[5\] Skew-Fit with Goal-Conditioned Reinforcement Learning

Thus far, we have presented Skew-Fit assuming that we have access to an oracle goal-reaching policy. In practice we do not have access to such an oracle goal-reaching policy, and so we must combine Skew-Fit with existing goal-conditioned reinforcement learning to maximize \(-H(G \mid S)\).

Maximizing \(-H(G \mid S)\) requires computing the density \( \log p(G \mid S) \), which may be difficult to compute without strong modeling assumptions. However, we show in Section \[B\] that using the following reward results in maximizing a lower bound for \(-H(G \mid S)\):

\[ r(S, G) = \log q(G \mid S). \]

Since Skew-Fit uses a generative model to propose goals, it is particularly natural to combine with reinforcement learning with imagined goals (RIG) \[Nair et al. (2018)\], though in theory any goal-conditioned method could be used. RIG is an efficient off-policy goal-conditioned method that fits a...
Figure 2: (Left) Learning curves for simulated continuous control experiments. Lower is better. We show the mean and standard deviation of 6 seeds and smooth temporally across 25 epochs within each seed. RIG + Skew-Fit consistently outperforms RIG and various baselines. See Appendix for description of each method. (Right) The first column displays example test goal images. The next two columns show an example image of the goal image reached by RIG + Skew-Fit and RIG. Under each image is the final distance in state space, though all tasks are trained from only images. The prior methods generally fail to generalize to these test goal images.

VAE and uses it to encode all observations and goals into a latent space. RIG also uses the generative model for both goal sampling and compute rewards, $\log p(G | S)$. Applying Skew-Fit to RIG then amounts to using Skew-Fit rather than MLE to train the VAE. We also replace the underlying RL algorithm with soft actor critic (Haarnoja et al., 2018).

6 Experiments

Figure 3: (Left) Picture of real-world door task setup. (Right) Learning curve for Real World Visual Door environment. We visually label a success if the policy opens the door to the target angle by the last state of the trajectory. Skew-Fit results in considerable sample efficiency gains over RIG.

Vision-based robot manipulation We evaluate Skew-Fit on simulated vision-based continuous control tasks. The agent must control a robot arm using only image observations, without access to any ground truth reward signal. Details of each environment and the chosen baselines are given in the Appendix. Training policies for these tasks is done in a completely unsupervised manner without access to any prior information about the state-space. However, to evaluate their performance, we evaluate their performance by sampling goal images from a uniform distribution. We report the final distance to the corresponding simulator state (e.g. distance of the puck to the target puck location). We see in Figure 2 that Skew-Fit significantly outperforms prior methods both in terms of task performance and sample complexity.

Real-world vision-based robotic manipulation Next, we demonstrate that Skew-Fit scales well to the real world with a door opening task. See Figure 7 for an image of the environment. We train an agent to control a Sawyer robot to open a door. We do not provide any goals to the agent and simply let it interact with the door to solve the door opening task from scratch, without any human guidance or reward signal. We train agents using RIG + Skew-Fit as well as RIG. As Figure 3 shows, standard RIG only starts to open the door consistently after five hours of training. In contrast, RIG + Skew-Fit learns to open the door after three hours of training and achieves a perfect success rate after five and a half hours of interaction time, demonstrating that Skew-Fit is a promising technique
for solving real world tasks without any human-provided reward function. Videos of our method solving this task, along with the simulated environments, can be viewed on our website.

Additional Experiments We also perform additional experiments including ablations and more thorough analysis in simple 2D environments in Section:

A Skew-Fit Analysis

In this section, we provide conditions under which $p_{\text{skewed}}$ converges to the uniform distribution over the state space $S$. Our most general result is stated as follows:

**Lemma A.1.** Let $S$ be a compact set. Define the set of distributions $Q = \{p : \text{support of } p \text{ is } S\}$. Let $F : Q \rightarrow Q$ be a continuous function and such that $\mathcal{H}(F(p)) \geq \mathcal{H}(p)$ with equality if and only if $p$ is the uniform probability distribution on $S$, $U_S$. Define the sequence of distributions $P = (p_1, p_2, \ldots)$ by starting with any $p_1 \in Q$ and recursively defining $p_{i+1} = F(p_i)$.

The sequence $P$ converges to $U_S$.

**Proof.** See C.1 \Box

The assumption that $S$ is compact is easily achieved in most application and makes $U_S$ well defined.

We will apply Lemma A.1 to be the map from $p_{\text{skewed}}$ to $p_{\text{skewed},+1}$ to show that $p_{\text{skewed}}$ converges to $U_S$. Skew-Fit produces a sequence of distributions $(p_{\phi_1}, p_{\text{emp}}, p_{\text{skewed}}, p_{\phi_2}, \ldots)$, and so we need to reason about the intermediate distributions, $p_{\phi_t}$ and $p_{\text{emp}}$. We begin with a few assumptions about the optimization method that maps $p_{\text{skewed}}$ to $p_{\phi_{t+1}}$ and the goal-conditioned policy that maps $p_{\phi_t}$ to $p_{\text{emp}}$, which are subroutines in Skew-Fit. We assume that these maps are continuous and do not decrease the entropy, i.e. $\mathcal{H}(p_{\text{emp},t+1}) \geq \mathcal{H}(p_{\phi_{t+1}}) \geq \mathcal{H}(p_{\text{skewed}})$. The continuity assumption states that the method used to fit $p_{\phi_{t+1}}$ and the goal-conditioned policy are well-behaved. Moreover, making a statement without the entropy assumption would be difficult: if the goal-conditioned policy ignored the goal and always entered the same state, or if the generative model only captured a single mode $p_{\text{skewed}}$, it would be challenging for any procedure to result in the uniform distribution.

Next, we assume the support of $p_{\phi_t}$ contains $S$, so that $p_{\text{skewed}}$ is well defined and a continuous function of $p_{\text{emp}}$ and $p_{\phi_t}$. Note that $p_{\phi_t}$ can have support larger than $S$, and so we can choose to optimize $p_{\phi_t}$ over any class of generative models with wide supports, without needing to know the manifold $S$.

To use Lemma A.1, we must show $\mathcal{H}(p_{\text{skewed}}) \geq \mathcal{H}(p_{\text{emp}})$ with equality if and only if $p_{\text{emp}} = U_S$. For the simple case when $p_{\phi_t} = p_{\text{emp}}$, identically at each iteration, we prove that this is true for any value of $\alpha \in [-1, 0]$ in Lemma C.2 of the Appendix.

The entropy of $p_{\text{skewed}}$ becomes more difficult to analyze when $p_{\phi_t} \neq p_{\text{emp}}$. However, we prove the following result:

**Lemma A.2.** Given two distribution $p_{\text{emp}}$ and $p_{\phi_t}$ where $p_{\text{emp}} \ll p_{\phi_t}$ and

$$0 < \text{Cov}_{S \sim p_{\text{emp}}} \left[ \log p_{\text{emp}}(S), \log p_{\phi_t}(S) \right],$$

(4)

define the distribution $p_{\text{skewed}}$, as in Equation 3. Let $\mathcal{H}_\alpha(\alpha)$ be the entropy of $p_{\text{skewed}}$ for a fixed $\alpha$. Then there exists a constant $\alpha < 0$ such that for all $\alpha \in [\alpha, 0)$,

$$\mathcal{H}(p_{\text{skewed}}) = \mathcal{H}_\alpha(\alpha) > \mathcal{H}(p_{\text{emp}}).$$

**Proof.** See C.4 \Box

While Lemma A.2 does not give an exact value for $\alpha$, it states that if we choose negative values of $\alpha$ that are small enough and if the log densities of $p_{\text{emp}}$ and $p_{\phi_t}$ are positively correlated, then we can guarantee that the entropy of $p_{\text{skewed}}$ will be higher then the entropy of $p_{\text{emp}}$. In practice, we expect the correlation to be frequently positive with an accurate goal-conditioned policy, since $p_{\text{emp}}$ is the set of states seen when trying to reach goals from $p_{\phi_t}$. Moreover, we found that $\alpha$ values as low as $\alpha = -1$ performed well. Lastly, the condition in Equation 4 is impossible to achieve if and only if $\log p_{\text{emp}}(S)$ is a constant, meaning that $p_{\text{emp}}$ is the uniform distribution.

In summary, we see that under certain assumptions, $p_{\text{skewed}}$ converges to $U_S$. Since we train each generative model $p_{\phi_{t+1}}$ by fitting it to $p_{\text{skewed}},$ we expect $p_{\phi_t}$ to also converge to $U_S$. We verify this numerically on both toy domains and realistic RL problems in our experiments.

---

We take $N \rightarrow \infty$ and refer to convergence in distribution.

$p \ll q$ means that $p$ is absolutely continuous with respect to $q$, i.e. $p(s) = 0 \implies q(s) = 0$. 

9
B  POLICY REWARD DERIVATION

Maximizing $I(G, S)$ can be done by simultaneously performing Skew-Fit and training a goal-conditioned policy to minimize $\mathcal{H}(G \mid S)$, or, equivalently, maximize $-\mathcal{H}(G \mid S)$. Maximizing $-\mathcal{H}(G \mid S)$ requires computing the density $\log p(G \mid S)$, which may be difficult to compute without strong modeling assumptions. However, for any distribution $q$, the following lower bound for $-\mathcal{H}(G \mid S)$ holds:

$$
-\mathcal{H}(G \mid S) = \mathbb{E}_{(G,S) \sim p_{\phi_t}, \pi} [\log q(G \mid S)] + D_{\text{KL}}(p \mid q)
\geq \mathbb{E}_{(G,S) \sim p_{\phi_t}, \pi} [\log q(G \mid S)]
$$

where $D_{\text{KL}}$ denotes Kullback–Leibler divergence. Thus to minimize $\mathcal{H}(G \mid S)$, we train a policy to maximize the following reward:

$$
r(S, G) = \log q(G \mid S).
$$

C  PROOFS

Let $q \ll p$ means that $q$ is absolutely continuous with respect to $p$, i.e. $p(x) = 0 \implies q(x) = 0$.

**Lemma C.1.** Let $S$ be a compact set. Define the set of distributions $Q = \{p : \text{support of } p \text{ is } S\}$.

Let $F : Q \mapsto Q$ be a continuous function and such that $\mathcal{H}(F(p)) \geq \mathcal{H}(p)$ with equality if and only if $p$ is the uniform probability distribution on $S$, $U_S$. Define the sequence of distributions $P = (p_1, p_2, \ldots)$ by starting with any $p_1 \in Q$ and recursively defining $p_{i+1} = F(p_i)$.

The sequence $P$ converges to $U_S$.

**Proof.** The uniform distribution $U_S$ is well defined since $S$ is compact. Because $S$ is a compact set, by Prokhorov’s Theorem [Billingsley, 2013], the set $Q$ is sequentially compact. Thus, $P$ has a convergent subsequence $P' = (p_{k_1}, p_{k_2}, \ldots) \subset P$ for $k_1 < k_2 < \ldots$ that converges to a distribution $p^* \in Q$. Because $F$ is continuous, $p^*$ must be a fixed point of $F$ since by the convergence mapping theorem, we have that

$$
\lim_{i \to \infty} p_{k_i} = p^* \implies \lim_{i \to \infty} F(p_{k_i}) = \mathcal{H}(p^*)
$$

and so

$$
p^* = \lim_{i \to \infty} p_{k_i} = \lim_{i \to \infty} F(p_{k_{i+1}}) = \mathcal{H}(p^*).
$$

The only fixed point of $F$ is $U_S$ since for any distribution $p$ that is not the uniform distribution, $U_S$, we have that $\mathcal{H}(F(p)) > \mathcal{H}(p)$ which implies that $F(p) \neq p$. Thus, $P'$ converges to the only fixed point, $U_S$. Since the entropy cannot decrease, then entropy of the distributions in $P$ must also converge to the entropy of $U_S$. Lastly, since entropy is a continuous function of distribution, $P$ must converge to $U_S$. $\square$

**Lemma C.2.** Assume the set $S$ has finite volume so that its uniform distribution $U_S$ is well defined and has finite entropy. Given any distribution $p(s)$ whose support is $S$, recursively define $p_\alpha$

$$
p_\alpha(s) = \frac{1}{Z_\alpha} p(s)^\alpha, \quad \forall s \in S
$$

where $Z_\alpha$ is the normalizing constant and $\alpha \in [0, 1]$.

---

7In the paper, $\alpha \in [-1, 0)$. However, when $p_{\text{emp}}_t = p_{\phi_t}$, Equation 3 becomes

$$
p_{\text{skewed},t}(s) = \frac{1}{Z_{\alpha'}} p_{\phi_t}(s) p_{\phi_t}(s)^\alpha, \quad \alpha \in [-1, 0)
\begin{align*}
&= \frac{1}{Z_{\alpha'}} p_{\phi_t}(s)^{\alpha'}, \quad \alpha' \in [0, 1)
\end{align*}
$$
For all $\alpha \in [0, 1)$,

$$\mathcal{H}(p_\alpha) \geq \mathcal{H}(p)$$

with equality if and only if $p$ is $U_S$, the uniform distribution $S$.

**Proof.** If $\alpha = 0$ or $p$ is the uniform distribution, the result is clearly true. We now study the case where $\alpha \in (0, 1)$ and $p \neq U_A$.

Define the one-dimensional exponential family $\{p_\theta : \theta \in [0, 1]\}$ where $p_\theta$ is

$$p_\theta(s) = e^{\alpha T(s) - A(\alpha + k(s))}$$

with log carrier density $k(s) = 0$, natural parameter $\alpha$, sufficient statistic $T(s) = \log p_t(s)$, and log-normalizer $A(\alpha) = \int_S e^{\alpha T(s)} ds$. As shown in [Nielsen & Nock, 2010], the entropy of a distribution from a one-dimensional exponential family with parameter $\alpha$ is given by:

$$\mathcal{H}_\theta^t(\alpha) \triangleq \mathcal{H}(p_\theta) = A(\alpha) - \alpha A'(\alpha)$$

The derivative with respect to $\alpha$ is then

$$\frac{d}{d\alpha} \mathcal{H}_\theta^t(\alpha) = -\alpha A''(\alpha)$$

$$= -\alpha \text{Var}_{s \sim p_\theta}[T(s)]$$

$$= -\alpha \text{Var}_{s \sim p_\theta}[\log p_t(s)]$$

$$\leq 0$$

where we use the fact that the $n$th derivative of $A(\alpha)$ is the $n$ central moment, i.e. $A''(\alpha) = \text{Var}_{s \sim p_\theta}[T(s)]$. Since variance is always non-negative, this means the entropy is monotonically decreasing with $\alpha$, and so

$$\mathcal{H}(p_\alpha) \geq \mathcal{H}(p_1) = \mathcal{H}(p)$$

with equality if and only if

$$\text{Var}_{s \sim p_\theta}[\log p(s)] = 0.$$

However, this only happens if $\log p(s)$ is constant over its support, i.e. it is the uniform distribution over its support.

We also prove the convergence directly for the (even more) simplified case when $p_{skewd_t} = p_{\phi_t+1} = p_{\text{emp}_t+1}$ using a similar technique:

**Lemma C.3.** Assume the set $S$ has finite volume so that its uniform distribution $U_S$ is well defined and has finite entropy. Given any distribution $p(s)$ whose support is $S$, recursively define $p_t$ with $p_1 = p$ and

$$p_{t+1}(s) = \frac{1}{Z_{t+1}} p_t(s)^\alpha, \quad \forall s \in S$$

where $Z_{t+1}$ is the normalizing constant and $\alpha \in (0, 1)$.

The sequence $(p_1, p_2, \ldots)$ converges to $U_S$, the uniform distribution $S$.

**Proof.** If $\alpha = 0$, then $p_2$ (and all subsequent distributions) will clearly be the uniform distribution. We now study the case where $\alpha \in (0, 1)$.

At each iteration $t$, define the one-dimensional exponential family $\{p_\theta^t : \theta \in [0, 1]\}$ where $p_\theta^t$ is

$$p_\theta^t(s) = e^{\theta T(s) - A(\theta) + k(s)}$$

with log carrier density $k(s) = 0$, natural parameter $\theta$, sufficient statistic $T(s) = \log p_t(s)$, and log-normalizer $A(\theta) = \int_S e^{\theta T(s)} ds$. As shown in [Nielsen & Nock, 2010], the entropy of a distribution from a one-dimensional exponential family with parameter $\theta$ is given by:

$$\mathcal{H}_\theta^t(\theta) \triangleq \mathcal{H}(p_\theta^t) = A(\theta) - \theta A'(\theta)$$
The derivative with respect to $\theta$ is then
\[
\frac{d}{d\theta} \mathcal{H}_\alpha^t (\theta) = -\theta A''(\theta)
\]
\[
= -\theta \text{Var}_{s \sim p_\theta^t} [T(s)]
\]
\[
= -\theta \text{Var}_{s \sim p_\theta^t} [\log p_t(s)]
\]
\[
\leq 0
\]  
where we use the fact that the $n$th derivative of $A(\theta)$ is the $n$ central moment, i.e. $A''(\theta) = \text{Var}_{s \sim p_\theta^t} [T(s)]$. Since variance is always non-negative, this means the entropy is monotonically decreasing with $\theta$. Note that $p_{t+1}$ is a member of this exponential family, with parameter $\theta = \alpha \in (0, 1)$. So
\[
\mathcal{H}(p_{t+1}) = \mathcal{H}_\alpha^t (\alpha) \geq \mathcal{H}_0^t (1) = \mathcal{H}(p_t)
\]
which implies
\[
\mathcal{H}(p_t) \leq \mathcal{H}(p_2) \leq \ldots
\]
This monotonically increasing sequence is upper bounded by the entropy of the uniform distribution, and so this sequence must converge.

The sequence can only converge if $\frac{d}{d\theta} \mathcal{H}_0^t (\theta)$ converges to zero. However, because $\alpha$ is bounded away from 0, Equation 5 states that this can only happen if
\[
\text{Var}_{s \sim p_\theta^t} [\log p_t(s)] \to 0.
\]  
(6)
Because $p_t$ has full support, then so does $p_\theta^t$. Thus, Equation 6 is only true if $\log p_t(s)$ converges to a constant, i.e. $p_t$ converges to the uniform distribution. \qed

**Lemma C.4.** Given two distribution $p(x)$ and $q(x)$ where $p \ll q$ and
\[
0 < \text{Cov}_p [\log p(X), \log q(X)]
\]  
(7)
define the distribution $p_\alpha$ as
\[
p_\alpha (x) = \frac{1}{Z_\alpha} p(x) q(x)^\alpha
\]
where $\alpha \in \mathbb{R}$ and $Z_\alpha$ is the normalizing factor. Let $\mathcal{H}_\alpha (\alpha)$ be the entropy of $p_\alpha$. Then there exists a constant $a > 0$ such that for all $\alpha \in [-a, 0)$,
\[
\mathcal{H}_\alpha (\alpha) > \mathcal{H}_\alpha (0) = \mathcal{H}(p).
\]  
(8)

**Proof.** Observe that $\{p_\alpha : \alpha \in [-1, 0]\}$ is a one-dimensional exponential family
\[
p_\alpha (x) = e^{\alpha T(x) - A(\alpha) + k(x)}
\]
with log carrier density $k(x) = \log p(x)$, natural parameter $\alpha$, sufficient statistic $T(x) = \log q(x)$, and log-normalizer $A(\alpha) = \int_X e^{\alpha T(x) + k(x)} dx$. As shown in Nielsen & Nock (2010), the entropy of a distribution from a one-dimensional exponential family with parameter $\alpha$ is given by:
\[
\mathcal{H}_\alpha (\alpha) \triangleq \mathcal{H}(p_\alpha) = A(\alpha) - \alpha A'(\alpha) - \mathbb{E}_{p_\alpha} [k(X)]
\]
The derivative with respect to $\alpha$ is then
\[
\frac{d}{d\alpha} \mathcal{H}_\alpha (\alpha) = -\alpha A''(\alpha) - \frac{d}{d\alpha} \mathbb{E}_{p_\alpha} [k(x)]
\]
\[
= -\alpha A''(\alpha) - \mathbb{E}_{p_\alpha} [k(x) (T(x) - A'(\alpha))]
\]
\[
= -\alpha \text{Var}_{p_\alpha} [T(x)] - \text{Cov}_{p_\alpha} [k(x), T(x)]
\]
where we use the fact that the $n$th derivative of $A(\alpha)$ give the $n$ central moment, i.e. $A'(\alpha) = \mathbb{E}_{p_\alpha} [T(x)]$ and $A''(\alpha) = \text{Var}_{p_\alpha} [T(x)]$. The derivative of $\alpha = 0$ is
\[
\frac{d}{d\alpha} \mathcal{H}_\alpha (0) = -\mathbb{C}_{p_0} [k(x), T(x)]
\]
\[
= -\mathbb{C}_{p_0} [\log p(x), \log q(x)]
\]
which is negative by assumption. Because the derivative at $\alpha = 0$ is negative, then there exists a constant $a > 0$ such that for all $\alpha \in [-a, 0]$, $\mathcal{H}_\alpha (\alpha) > \mathcal{H}_\alpha (0) = \mathcal{H}(p)$. \qed
D Environment Details

Point-Mass: In this environment, an agent must learn to navigate a square-shaped corridor (see Figure 6). The observation is the 2D position, and the agent must specify a velocity as the 2D action. The reward at each time step is the negative distance between the achieved position and desired position.

Visual Pusher: A MuJoCo environment with a 7-DoF Sawyer arm and a small puck on a table that the arm must push to a target position. The agent controls the arm by commanding $x,y$ position for the end effector (EE). The underlying state is the EE position, $e$ and puck position $p$. The evaluation metric is the distance between the goal and final puck positions. The hand goal/state space is a $10\times10$ cm$^2$ box and the puck goal/state space is a $30\times20$ cm$^2$ box. Both the hand and puck spaces are centered around the origin. The action space ranges in the interval $[-1, 1]$ in the $x$ and $y$ dimensions.

Visual Door: A MuJoCo environment with a 7-DoF Sawyer arm and a door on a table that the arm must pull open to a target angle. Control is the same as in Visual Pusher. The evaluation metric is the distance between the goal and final door angle, measured in radians. In this environment, we do not reset the position of the hand or door at the end of each trajectory. The state/goal space is a $5\times20\times15$ cm$^3$ box in the $x, y, z$ dimension respectively for the arm and an angle between $[0, .83]$ radians. The action space ranges in the interval $[-1, 1]$ in the $x, y$ and $z$ dimensions.

Visual Pickup: A MuJoCo environment with the same robot as Visual Pusher, but now with a different object. The object is cube-shaped, but a larger intangible sphere is overlaid on top so that it is easier for the agent to see. Moreover, the robot is constrained to move in 2 dimension: it only controls the $y,z$ arm positions. The $x$ position of both the arm and the object is fixed. The evaluation metric is the distance between the goal and final object position. For the purpose of evaluation, 75% of the goals have the object in the air and 25% have the object on the ground. The state/goal space for both the object and the arm is 10cm in the $y$ dimension and 13cm in the $z$ dimension. The action space ranges in the interval $[-1, 1]$ in the $y$ and $z$ dimensions.

Real World Visual Door: A Rethink Sawyer Robot with a door on a table. The arm must pull the door open to a target angle. The agent controls the arm by commanding the $x,y,z$ velocity of the EE. Our controller commands actions at a rate of up to 10Hz with the scale of actions ranging up to 1cm in magnitude. The underlying state and goal is the same as in Visual Door. Again we do not reset the position of the hand or door at the end of each trajectory. We obtain images using a Kinect Sensor and our robotic control code can be found at [https://github.com/mdalal2020/sawyer_control.git](https://github.com/mdalal2020/sawyer_control.git). The state/goal space for the environment is a $10\times10\times10$ cm$^3$ box. The action space ranges in the interval $[-1, 1]$ (in cm) in the $x, y$ and $z$ dimensions. The door angle lies in the range $[0, 30]$ degrees.

![Visual Object Pickup](image)

Figure 5: Cumulative total pickups during exploration for each method. RIG + Skew-Fit quickly learns to learn to pick up the object while the baselines fail to pay attention to the object.

E Additional Experiment and Experiment Details

E.1 Baselines

First, we compare to standard RIG, without Skew-Fit. We also compare to hindsight experience replay (HER) [Andrychowicz et al. (2017)], which relabels goals based on states seen in the rest of
the trajectory. While the original HER paper operates directly on the raw state space, we were unable to get HER to learn from pixels. We instead ran HER on the same latent space used as our method, and use the learned generative model to sample goals for exploration. We denote this baseline RIG + HER. Florensa et al. (2018b) samples goals from a GAN based on the difficulty of reaching the goal. We include a comparison against this method by replacing $p_\phi$ with the GAN and label it RIG + AutoGoal. We compare to Warde-Farley et al. (2018), which uses a non-parametric approach based on clustering to sample goals and a state discriminator to compute rewards. When trained either on images or the RIG latent state, we were unable to obtain good results, and have included the latter as RIG + DISCERN. We also compare to the goal proposal mechanism proposed by Warde-Farley et al. (2018) without the discriminative reward in DISCERN, which we label RIG + DISCERN-g. Lastly, we compare our method to two exploration methods based on reward bonuses: ICM (Pathak et al., 2017), which rewards an agent for visiting states that are difficult to predict, and # Exploration (Tang et al., 2017), which rewards an agent for visiting novel states, where novelty is measured using a hash table. These two baselines are denoted RIG + ICM and RIG + #Exploration respectively.

E.2 2D NAVIGATION EXPERIMENTS

We initialize the VAE to only output points in the bottom left corner of the environment. Both the encoder and decoder have ReLU hidden activations, 2 hidden layers with 32 units, and no output activations. The VAE has a latent dimension of 16 and a Gaussian decoder trained with mean-squared error loss, batch size of 500, and 100 epochs per iteration. For Skew-Fit hyperparameters, $\alpha = -0.5$ and $N = 10000$.

For the RL version of this task, the VAE was trained in the same way. The RL hyperparameters are listed in Table 1. Our experimental evaluation of Skew-Fit aims to study the following empirical questions: (1) Can Skew-Fit learn a generative model to find the uniform distribution over the set of valid states? (2) Does Skew-Fit work on high dimensional state spaces, such as images? (3) When combined with goal-conditioned RL, can Skew-Fit enable agents to autonomously set and learn to reach a diverse set of goals?

Section E.3 studies the first question in the context of a simple 2-dimensional navigation environment. Section E.4 studies the second question by applying Skew-Fit to both simulated and real-world images in an unsupervised learning setting, without a goal-conditioned policy. Finally, Section ?? analyzes the performance of Skew-Fit when combined with RIG on a variety of simulated tasks, vision-based robot manipulation tasks.

![Figure 6: (Left) The set of final states visited by our agent and MLE over the course of training. In contrast to MLE, our method quickly approaches a uniform distribution over the set of valid states. (Right) The entropy of the sample data distribution, which quickly reaches its maximum for Skew-Fit. The entropy was calculated via discretization onto a 60 by 60 grid.](image)

E.3 SKEW-FIT ON SIMPLIFIED RL ENVIRONMENT

We first analyze the effect of Skew-Fit for learning a goal distribution in isolation from training a goal-reaching policy. To this end, we study an idealized example where the policy is a hand-designed, near-perfect goal-reaching policy.
The MDP is defined on a 2-by-2 unit square-shaped corridor (see Figure 6). At the beginning of an episode, the agent begins in the bottom-left corner and samples a goal from a goal distribution $p_{\theta_t}$. To model an imperfect policy, we add zero-mean Gaussian noise to this sampled goal with a standard deviation of 0.05. The policy reaches the state that is closest to this noisy goal and inside the corridor, giving us a state $S$ to add to our empirical distribution. After collecting $N = 10000$ states using the process above, we train $p_{\theta_{t+1}}$ on the collected states and then repeat the entire procedure, this time sampling goals from $p_{\theta_{t+1}}$. We compare Skew-Fit to a goal sampling distribution that is only trained using maximum likelihood estimation (MLE).

As seen in Figure 6, Skew-Fit results in learning a high entropy, near-uniform distribution over the state space. In contrast, MLE only models the states that are explored by the initial noise of the policy, resulting in the policy only setting goals in and exploring the bottom left corner. These results empirically validate that naively using previous experience to set goals will not result in diverse exploration and that Skew-Fit results in a maximum-entropy goal-sampling distribution.

As seen in Figure 6, Skew-Fit results in learning a high entropy, near-uniform distribution over the state space. In contrast, MLE only models the states that are explored by the initial noise of the policy, resulting in the policy only setting goals in and exploring the bottom left corner. These results empirically validate that naively using previous experience to set goals will not result in diverse exploration and that Skew-Fit results in a maximum-entropy goal-sampling distribution.

![Figure 6](image)

**Figure 6:** Here we display all four of our continuous control environments. In the top left corner, **Visual Door**, the simulated door opening environment. In the top right, **Visual Pickup**, the simulated object pick up task. The bottom left display **Visual Pusher**, the simulated puck pushing environment while the bottom right is **Real World Visual Door**, the real world door opening task. See appendix for more details.

![Figure 8](image)

**Figure 8:** Samples from a generative model $p_\phi$ when trained with (a) Skew-Fit and with (b) maximum likelihood estimation trained on images from the simulated door opening task. The models are trained on a dataset collected by executing a random policy in the environment, which results in mostly images with a closed door and only occasional images with the door open. Note that the Skew-Fit samples are substantially more diverse, meaning that if $p_\phi$ were used to sample goals, it would encourage the agent to practice opening the door more frequently.
E.4 Modeling Visual Observations

We would like to use Skew-Fit to learn maximum-entropy distributions over complex, high-dimensional state spaces, where we cannot manually design these uniform distributions. The next set of experiments study how Skew-Fit can be used to train a generative model to sample diverse images when trained on an imbalanced dataset. For these experiments, we use a simulated MuJoCo [Todorov et al., 2012] environment and real environment that each consists of a 7 degree of freedom robot arm in front of a door that it can open. See Figure 7 for a visualization of the simulated and real-world door environment, and the Appendix for more details on the environment.

We generate a dataset of images from the environment by running a policy that samples actions uniformly at random. Such a policy represents a particularly challenging setting for standard VAE training methods: a policy that chooses random actions does not visit uniformly random states, but rather states that are heavily biased toward ones that resemble the initial state. In the door opening environment, this means that many of the samples have the door in the initial closed position, and only the robot’s arm moves. We then train two generative models on these datasets: one using Skew-Fit and another using MLE. For our generative model, we use the same generative model as the one in RIG, a variational autoencoder [Kingma & Welling, 2014]. To estimate the likelihood of our data, we use Monte Carlo estimation and importance sampling to marginalize the latent variables. See Appendix Section E.7 for experimental details.

In this experiment, we do not train a goal-conditioned policy, and instead only study how Skew-Fit can be used to effectively “balance” this dataset. As can be seen in Figure 8 and Figure 9b, the samples produced by the model trained with Skew-Fit generally have a much wider range of door angles, while the model trained with MLE only captures a single mode of the door, both for simulated and real-world images.

Figure 9: (a) Comparison of Skew-Fit vs MLE goal sampling on final distance to goal on RL version of the pointmass environment. Skew-Fit consistently learns to solve the task, while MLE often fails. (b) Heatmaps of final distance to each possible goal location for Skew-Fit and MLE. Skew-Fit learns a good policy over the entire state space, but MLE performs poorly for states far away from the starting position.

E.5 2D Navigation

We now provide a simple experiment that combines Skew-Fit with a goal-conditioned policy that is trained. We reproduce the 2D navigation environment experiment from Section E.3 and replace the oracle goal-reacher with a goal-reaching policy that is simultaneously trained. The policy outputs velocities with maximum speed of one. Evaluation goals are chosen uniformly over the valid states. In Figure 9a, we can see that a policy trained with a goal distribution trained by Skew-Fit consistently learns to reach all goals, whereas a goal distribution trained with MLE results in a policy that fails to reach states far from the starting position.
E.6 Sensitivity Analysis

We study the sensitivity of the $\alpha$ hyperparameter by testing values of $\alpha \in [0, -0.25, -0.5, -0.75, -1]$ on the Visual Door and Visual Pusher task. The results are included in the Appendix in Figure 10 and shows that our method is relatively robust to different parameters of $\alpha$, particularly for the more challenging Visual Pusher task.

![Visual Door Alpha Ablation](image)

![Visual Pusher Alpha Ablation](image)

Figure 10: We sweep different values of $\alpha$ on (a) Visual Door and (b) Visual Pusher. Skew-Fit helps the finally performance marginally on the Visual Door task, and even degrades performance if $\alpha$ is large in magnitude. In the more challenging Visual Pusher task, we see that Skew-Fit consistently helps and halves the final distance.

E.7 Vision-Based Continuous Control Experiments

For our underlying RL algorithm, we use a modified version of soft actor critic (SAC) with automated entropy tuning [Haarnoja et al. (2018)] and twin Q-functions [Fujimoto et al. (2018)]. This is in contrast to the original RIG [Nair et al. (2018)] paper which used TD3 [Fujimoto et al. (2018)]. We found that maximum entropy policies in general improved the performance of RIG, and that we did not need to add noise on top of the stochastic policy’s noise. For our RL network architectures and training scheme, we use fully connected networks for the policy, Q-function and value networks with two hidden layers of size 400 and 300 each. We also delay training any of these networks for 10000 time steps in order to collect sufficient data for the replay buffer as well as to ensure the latent space of the VAE is relatively stable (since we train the VAE online in this setting). As in RIG, we train a goal-conditioned value functions [Schaul et al. (2015)] using hindsight experience replay [Andrychowicz et al. (2017)], relabelling 50% of exploration goals as goals sampled from the VAE prior $\mathcal{N}(0, 1)$ and 30% from future goals in the trajectory.

In our experiments, we use an image size of 48x48. For our VAE architecture, we use a modified version of the architecture used in the original RIG paper [Nair et al. (2018)]. Our VAE has three convolutional layers with kernel sizes: 5x5, 3x3, and 3x3, number of output filters: 16, 32, and 64 and strides: 3, 2, and 2. We then have a fully connected layer with the latent dimension number of units, and then reverse the architecture with de-convolution layers. We vary the latent dimension of the VAE, the $\beta$ term of the VAE and the $\alpha$ term for Skew-Fit based on the environment. Additionally, we vary the training schedule of the VAE based on the environment. See the table at the end of the

*aWe expect similar performance had we used SAC.

appendix for more details. Our VAE has a Gaussian decoder with identity variance, meaning that we train the decoder with a mean-squared error loss.

We estimate the density under the VAE by using a sample-wise approximation to the marginal over $x$ estimated using importance sampling:

$$p_{\theta_t}(x) = \mathbb{E}_{z \sim q_{\theta_t}(z|x)} \left[ \frac{p(z)}{q_{\theta_t}(z|x)} p_{\psi_t}(x | z) \right]$$

$$\approx \frac{1}{N} \sum_{i=1}^{N} \left[ \frac{p(z)}{q_{\theta_t}(z|x)} p_{\psi_t}(x | z) \right].$$

where $q_{\theta}$ is the encoder, $p_{\psi}$ is the decoder, and $p(z)$ is the prior, which in this case is unit Gaussian. In practice we found that sampling $N = 10$ latents for estimating the density to work well in practice.

When training the VAE alongside RL, we found the following two schedules to be effective for different environments:

1. For first $5K$ steps: Train VAE using standard MLE training every 500 time steps for 1000 batches. After that, train VAE using Skew-Fit every 500 time steps for 200 batches.
2. For first $5K$ steps: Train VAE using standard MLE training every 500 time steps for 1000 batches. For the next $45K$ steps, train VAE using Skew-Fit every 500 steps for 200 batches. After that, train VAE using Skew-Fit every 1000 time steps for 200 batches.

We found that initially training the VAE without Skew-Fit improved the stability of the algorithm. This is due to the fact that density estimates under the VAE are extremely unstable and inaccurate during the early phases of training. As a result, we simply train using MLE training at first, and once the density estimates stabilize, we perform Skew-Fit. Table 2 lists the hyper-parameters that were shared across the continuous control experiments. Table 3 lists hyper-parameters specific to each environment.
Figure 11: Example reached goals by RIG + Skew-Fit and RIG. The first column of each environment section specifies the target goal while the second and third columns show reached goals by RIG + Skew-Fit and RIG. Both methods learn how to reach goals close to the initial position, but only RIG + Skew-Fit learns to reach the more difficult goals.
